

THE HISTOGRAM OF PARTITIONED LOCALIZED IMAGE TEXTURES

Eric Brewster

Dr. James Keller, Thesis Supervisor

ABSTRACT

Humans are uniquely equipped to distinguish texture; however, computers are more equipped to automate the process. Computers accomplish this by taking images and extracting meaningful features that describe their texture. Some of these features are the Haralick texture features, local binary pattern (LBP), and the local direction pattern (LDP). We propose a new texture feature called the histogram of partitioned localized image textures (HoPLIT). This feature utilizes a set of filters, and generates filter response vectors at every pixel location. Using the bag-of-words model, a codebook is created by partitioning a subset of response vectors from the entire data set. The partitions are represented by their mean texture and thus a word in the codebook. A histogram descriptor for an image is the frequency of pixels that belong to each partition. These features are applied to a texture classification and segmentation problem as well as object detection. The HoPLIT feature does very well classifying texture as well as segmenting large texture mosaics. HoPLIT also shows a surprising robustness to noise. Object detection proves to be slightly more difficult than texture classification for HoPLIT. However, it continues to outperform LBP and LDP.
