Received 17 December 1996, in final form 4 April 1997

Abstract. The method of averaging is used to investigate the phenomenon of capture into resonance for a model that describes a Keplerian binary system influenced by radiation damping and external normally incident periodic gravitational radiation. The dynamical evolution of the binary orbit while trapped in resonance is elucidated using a second-order partially averaged system. This method provides a theoretical framework which can be used to explain the main evolutionary dynamics of a physical system that has been trapped in resonance.

1. Introduction

In two previous papers [1, 2], we considered the long-term nonlinear evolution of a Keplerian binary system that is perturbed by a normally incident periodic gravitational wave, and in a recent work [3] we considered the additional effect of radiation damping, which is of interest in connection with the observed behaviour of the Hulse–Taylor binary pulsar PSR 1913+16 [4, 5]. These studies have been concerned with the issue of *gravitational ionization*, i.e. the possibility that an external periodic gravitational wave could ionize a Keplerian binary system over a long period of time. The impetus for this subject has come from the close conceptual analogy between gravitational ionization and a fundamental physical process, namely, the electromagnetic ionization of a hydrogen atom. That is, in these studies one hopes to learn about the disposition of gravitational radiation to transfer energy and angular momentum in its interaction with matter. In our recent investigation [3], we encountered an interesting dynamical phenomenon connected with the passage of the binary orbit through resonance. As the binary system loses energy and angular momentum by emitting gravitational waves, its semimajor axis and eccentricity decrease monotonically on average; however, this process of inward spiralling could stop if the system is captured into a resonance. The resonance condition fixes the semimajor axis; therefore, if the semimajor axis decreases to the resonant value and the orbit is trapped, it then maintains this value *on average* while the external perturbation deposits energy into the system to compensate for the radiation damping *on average*. It turns out that along with this energy deposition, the

external tidal perturbation can also deposit angular momentum into the binary orbit so that its eccentricity decreases considerably during the passage through resonance. This was the situation for the particular instances of resonance trapping reported in [3]. In general, the orbital angular momentum can increase or decrease while the orbit is trapped in resonance. Figure 1 depicts passage through a $(1 : 1)$ resonance in which the eccentricity decreases. A similar phenomenon, but with an initial increase in eccentricity that soon levels off once the resonance is established, has been reported in the recent numerical study of the three-body problem by Melita and Woolfson [6]. The increase in eccentricity can occur over a long time-scale in a $(4 : 1)$ resonance in our model as depicted in figure 3. The dynamical phenomena associated with an orbit trapped in a resonance occur over many Keplerian periods of the osculating ellipse; therefore, it is natural to average the dynamical equations over the orbital period at resonance. This partial averaging removes the ‘fast’ motion and allows us to see more clearly the ‘slow’ motion during trapping. It is possible to provide a description of the slow motion as well as a theoretical justification for the transfer of angular momentum by means of the method of second-order partial averaging near a resonance. The purpose of the present paper is to study this phenomenon theoretically using the method of averaging for the resonances that occur in a Keplerian binary that is perturbed by the emission and absorption of gravitational radiation.

Figure 1. The plots are for system (4) with parameter values $\epsilon = 10^{-4}$, $\delta/\epsilon = 10^{-3}$, $\alpha = 1$, $\beta = 0$, $\rho = 0$, and $\Omega = 1$. (a) $L = a^{1/2}$ versus time for the initial conditions $(p_r, p_\theta, r, \theta)$ equal to $(0.2817, 0.6389, 1.6628, 2.9272)$. (b) Eccentricity versus time and (c) G versus L . Here, $L_* = 1$ corresponds to a $(1 : 1)$ resonance, $1/L_*^3 = \Omega$.

Let us consider the simplest model involving a perturbed Keplerian (i.e. nonrelativistic) binary that contains the effects of radiation reaction damping and external tidal perturbation in the lowest (i.e. quadrupole) order. The tidal perturbation could be due to external masses and gravitational radiation; in fact, in what follows we choose a normally incident periodic gravitational wave for the sake of simplicity [3]. Moreover, the wavelength of the external radiation is assumed to be much larger than the dimensions of the binary system. The gravitational wave potentials that characterize this external perturbation in the transverse traceless gauge have an overall amplitude given by a positive constant ϵ that is usually very small compared to unity; therefore, the external perturbation is considered only to first order in ϵ . For instance, it is expected that for realistic sources of gravitational radiation $\epsilon \sim 10^{-20}$, though direct observational evidence for gravitational waves does not exist at present. The Keplerian binary orbit under the combined perturbations due to the emission and absorption of gravitational radiation in the quadrupole approximation is given in our model by the equation of relative motion

$$\frac{d^2 x^i}{dt^2} + \frac{kx^i}{r^3} + \mathcal{R}^i = -\epsilon \mathcal{K}_{ij} x^j, \quad (1)$$

where $\mathbf{x}(t)$ is the relative two-body orbit, $r = |\mathbf{x}|$ and $k = G_0(m_1 + m_2)$. The binary consists of two point masses m_1 and m_2 , $m_1 + m_2 = M$, that move according to $\mathbf{x}_1(t) = (m_2/M)\mathbf{x}(t)$ and $\mathbf{x}_2(t) = -(m_1/M)\mathbf{x}(t)$, so that the centre of mass of the system is at the origin of the coordinates. In fact, the centre of mass of the binary can be taken to be at rest in the approximation under consideration here as explained in our recent paper [3]. This is an interesting consequence of our simple model in which the post-Newtonian gravito-electromagnetic effects have been neglected in the two-body system, while the strengths of the radiative perturbations have been taken into account only to first order and the radiative effects have been treated only at the quadrupole level. In this way, gravitational waves emitted by the binary system carry energy and angular momentum away from the system but not linear momentum; similarly, in absorption the system exchanges energy and angular momentum with the incident radiation field but not linear momentum. The Newtonian centre of mass of the binary system is thus unaffected by the radiative perturbations in our model. The explicit expressions for \mathcal{R} and \mathcal{K} are

$$\mathcal{R} = \frac{4G_0^2 m_1 m_2}{5c^5 r^3} \left[\left(12v^2 - 30\dot{r}^2 - \frac{4k}{r} \right) \mathbf{v} - \frac{\dot{r}}{r} \left(36v^2 - 50\dot{r}^2 + \frac{4k}{3r} \right) \mathbf{x} \right], \quad (2)$$

and

$$\mathcal{K} = \Omega^2 \begin{bmatrix} \alpha \cos \Omega t & \beta \cos (\Omega t + \rho) & 0 \\ \beta \cos (\Omega t + \rho) & -\alpha \cos \Omega t & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad (3)$$

where $\mathbf{v} = \dot{\mathbf{x}}(t)$, an overdot denotes differentiation with respect to time, α and β are of the order of unity and are the amplitudes of the two independent states of linear polarization of the normally incident wave, ρ is a constant phase and Ω is the frequency of the external wave.

It is interesting to transform the dynamical system (1)–(3) into dimensionless form. To accomplish this, let $\mathbf{x} \rightarrow R_0 \mathbf{x}$ and $t \rightarrow T_0 t$ where R_0 and T_0 are scale parameters. Under this transformation, $k \rightarrow k T_0^2 / R_0^3$ and \mathcal{K} remains unchanged if we let $\Omega \rightarrow \Omega / T_0$. Let us further restrict R_0 and T_0 by the relation $k T_0^2 = R_0^3$, so that we can set $k = 1$ in the dynamical equations; for instance, this condition is satisfied if R_0 is the initial semimajor axis of the unperturbed Keplerian orbit and $2\pi T_0$ is its period. We thus deal with dimensionless quantities in the following analysis; however, our results can be simply rescaled in order

to correspond to physical quantities. Furthermore, the dynamical system (1)–(3) is planar; therefore, it is convenient to express these dimensionless equations in polar coordinates (r, θ) in the orbital plane. The result is

$$\begin{aligned}\frac{dr}{dt} &= p_r, \\ \frac{d\theta}{dt} &= \frac{p_\theta}{r^2}, \\ \frac{dp_r}{dt} &= -\frac{1}{r^2} + \frac{p_\theta^2}{r^3} + \frac{4\delta p_r}{r^3} \left(p_r^2 + 6\frac{p_\theta^2}{r^2} + \frac{4}{3r} \right) \\ &\quad - \epsilon r \Omega^2 [\alpha \cos 2\theta \cos \Omega t + \beta \sin 2\theta \cos (\Omega t + \rho)], \\ \frac{dp_\theta}{dt} &= \frac{2\delta p_\theta}{r^3} \left(9p_r^2 - 6\frac{p_\theta^2}{r^2} + \frac{2}{r} \right) + \epsilon r^2 \Omega^2 [\alpha \sin 2\theta \cos \Omega t - \beta \cos 2\theta \cos (\Omega t + \rho)],\end{aligned}\tag{4}$$

where δ , $0 < \delta \ll 1$, is the dimensionless strength of the radiation reaction and is given by

$$\delta = \frac{4G_0^2 m_1 m_2}{5c^5 T_0 R_0},\tag{5}$$

while ϵ , $0 < \epsilon \ll 1$, is the dimensionless strength of the external periodic perturbation. The nature of the perturbation parameter δ becomes clear once R_0 is taken to be the semimajor axis of the unperturbed Keplerian system. Equation (5) can then be written as

$$\delta = \frac{\sqrt{2}}{40} \left(\frac{4\mu}{M} \right) q_0^{5/2},$$

where μ is the reduced mass of the binary and $q_0 = (2G_0 M/c^2)/R_0$. Here $4\mu \leq M$ in any case and $2G_0 M/c^2$ is the gravitational radius of the binary system so that the quotient q_0 , $0 < q_0 < 1$, indicates how relativistic the system is at the outset; in fact, the system is essentially a black hole for $q_0 \sim 1$. It follows that $\delta < \sqrt{2}/40$ for any physical system; indeed, for the Sun–Mercury system $q_0 \approx 5 \times 10^{-8}$ and $\delta \approx 10^{-26}$, while for the Hulse–Taylor relativistic binary pulsar $q_0 \approx 4 \times 10^{-6}$ and $\delta \approx 10^{-15}$. In this paper, we let $\delta = \epsilon \Delta$, where Δ , $0 < \Delta < \infty$, is a parameter that is fixed in the system; in this way, we avoid dealing with a two-parameter (ϵ, δ) perturbation problem. In particular, we consider only perturbations that correspond to fixed directions from the origin of this parameter space. The full two-parameter problem would require the consideration of perturbations corresponding to all curves in the parameter space.

In the absence of radiative perturbations ($\epsilon = 0$ and $\delta = 0$), the dynamical system (4) describes a Keplerian ellipse. It is therefore useful to express the dynamical equations (4) in terms of Delaunay variables that are closely related to the elements of the osculating ellipse. This is the ellipse that the relative orbit would describe at time t , if the perturbations were turned off at t . The osculating ellipse always has the same focus, which is taken to be the origin of the (polar) coordinates in the space of relative coordinates. Let the state of relative motion be described by (x, v) , or equivalently $(r, \theta, p_r, p_\theta)$, at time t ; then, the energy of the motion fixes the semimajor axis a of the osculating ellipse and its eccentricity is subsequently fixed by the orbital angular momentum p_θ . Only two angles are left to determine the osculating ellipse completely: the orientation of the ellipse in the orbital plane given by g and the position on the ellipse measured from the periastron given by the true anomaly \hat{v} . The latter is obtained from $p_r p_\theta = e \sin \hat{v}$ and the equation of the ellipse

$$\frac{p_\theta^2}{r} = 1 + e \cos \hat{v},$$

and the former from $\theta - \hat{v}$. The relevant Delaunay ‘action-angle’ variables (L, G, ℓ, g) are thus defined by [7, 8]

$$\begin{aligned} L &:= a^{1/2}, & G &:= p_\theta = L(1 - e^2)^{1/2}, \\ \ell &:= \hat{u} - e \sin \hat{u}, & g &:= \theta - \hat{v}, \end{aligned} \quad (6)$$

where \hat{u} is the eccentric anomaly of the osculating ellipse, $r = a(1 - e \cos \hat{u})$ and ℓ is the mean anomaly. The dynamical system (4) in terms of Delaunay variables is given briefly in appendix A and used in the following section.

The Delaunay equations of motion are useful for the investigation of periodic orbits using the Poincaré surface of section technique [9]. It has been shown in [3] that nearly resonant periodic orbits exist in system (4) for sufficiently small ϵ and Δ . These correspond to $(m : 1)$ resonances, where $(m : n)$ refers to the resonance condition $m\omega = n\Omega$. Here m and n are two relatively prime integers and $\omega = 1/L^3$ is the Keplerian frequency of the orbit. A linear perturbation treatment [10] first revealed resonant absorption at $(m : 1)$ resonances. There could, in principle, be other periodic orbits whose existence is not revealed by our method [11, 1].

In our numerical investigation of the simple nonlinear model described above, we found [3] instances of resonance trapping during which the behaviour of the osculating orbit could not be inferred in a simple manner on the basis of equation (4). However, the dynamics of the *averaged* equations in resonance is simpler to analyse and it turns out that our numerical results [3] can be explained adequately using the second-order partially averaged dynamics. The phenomenon of resonance trapping appears to be of basic significance for the origin of the solar system; therefore, it is worthwhile developing a general theoretical framework for the study of the evolutionary dynamics while trapped in resonance.

The *dynamics* of a system when it is locked in resonance is interesting in any circumstance involving more than one degree of freedom; for instance, let us suppose that the resonance condition fixes an action variable—say, energy—and for a one-dimensional motion this would then imply that the state of the system at resonance is definite. However, if other action variables are present, they will not necessarily remain fixed while the system is trapped in resonance. Instead, the state of the system will, in general, vary and its dynamics at resonance is best investigated using the method of averaging. This is a generalization of the simple procedure that is commonly employed in Hamiltonian dynamics: the Hamiltonian is averaged over certain ‘fast’ variables and the resulting averaged Hamiltonian is used to derive new dynamical equations that presumably describe the ‘slow’ motion in a certain averaged sense. The general method is described in appendix B and it is applied to the dissipative dynamical system under consideration here in the rest of this paper.

Resonance is a general and significant physical phenomenon and the description of the state of a physical system while trapped in resonance is of intrinsic importance. The inherent dynamics at resonance is trivial for a one-dimensional oscillator, but is rich in physical consequences for higher-dimensional systems. While the general methods described here could be applied to a wide variety of physical problems, we confine our attention to a single model. Our results may, however, be of qualitative interest in dealing with the three-body problems that arise in the discussions of the origin of structure in the solar system.

The present paper relies on the results of our recent work [3]. We have repeated here only what is needed for the discussion of the dynamics at resonance; for a more precise and complete presentation of the background material, our papers [1–3] should be consulted.

Finally, a basic limitation of our model should be noted. The only damping mechanism that we take into account is the gravitational radiation reaction; this is consistent with our assumption that the binary consists of Newtonian point masses moving in vacuum

except for the presence of background gravitational radiation. In this model, a theorem of Neishtadt can be used to show that resonance trapping is a rather rare phenomenon [3]. However, taking due account of the finite size and structure of astronomical bodies and the existence of an ambient medium, we would have to include in our model—among other things—the additional damping effects of tidal friction as well as the various drag effects of the ambient medium and electromagnetic radiation (cf, for instance, [6, 12–15]). These additional frictional effects could well combine to violate the condition N of Neishtadt's theorem [3, 16]. Thus, resonance trapping may not be so rare in astrophysics after all [17]. Inclusion of these additional effects is beyond the scope of our work.

2. Partial averaging near a resonance

We will consider the dynamics of the model system (4) that is derived in [3]. It has the following form when expressed in the Delaunay elements for the Kepler problem under consideration (cf appendix A):

$$\begin{aligned}\dot{L} &= -\epsilon \frac{\partial \mathcal{H}_{\text{ext}}}{\partial \ell} + \epsilon \Delta f_L, \\ \dot{G} &= -\epsilon \frac{\partial \mathcal{H}_{\text{ext}}}{\partial g} + \epsilon \Delta f_G \\ \dot{\ell} &= \frac{1}{L^3} + \epsilon \frac{\partial \mathcal{H}_{\text{ext}}}{\partial L} + \epsilon \Delta f_\ell, \\ \dot{g} &= \epsilon \frac{\partial \mathcal{H}_{\text{ext}}}{\partial G} + \epsilon \Delta f_g,\end{aligned}\tag{7}$$

where $\epsilon \mathcal{H}_{\text{ext}}$ is the Hamiltonian corresponding to the external perturbation and

$$\mathcal{H}_{\text{ext}} = \frac{1}{2} \Omega^2 [\alpha \mathcal{C}(L, G, \ell, g) \cos \Omega t + \beta \mathcal{S}(L, G, \ell, g) \cos(\Omega t + \rho)].\tag{8}$$

Here

$$\begin{aligned}\mathcal{C}(L, G, \ell, g) &= \frac{5}{2} a^2 e^2 \cos 2g + a^2 \sum_{\nu=1}^{\infty} (A_\nu \cos 2g \cos \nu \ell - B_\nu \sin 2g \sin \nu \ell), \\ \mathcal{S}(L, G, \ell, g) &= \frac{5}{2} a^2 e^2 \sin 2g + a^2 \sum_{\nu=1}^{\infty} (A_\nu \sin 2g \cos \nu \ell + B_\nu \cos 2g \sin \nu \ell), \\ A_\nu &= \frac{4}{\nu^2 e^2} [2\nu e(1 - e^2) J'_\nu(\nu e) - (2 - e^2) J_\nu(\nu e)], \\ B_\nu &= -\frac{8}{\nu^2 e^2} (1 - e^2)^{1/2} [e J'_\nu(\nu e) - \nu(1 - e^2) J_\nu(\nu e)],\end{aligned}\tag{9}$$

where J_ν is the Bessel function of the first kind of order ν and $e = (L^2 - G^2)^{1/2}/L$. The radiation reaction ‘forces’ f_D , $D \in \{L, G, \ell, g\}$, are certain complicated functions of the Delaunay variables given in appendix A. In fact, we will only require the averages of the f_D given by

$$\bar{f}_D := \frac{1}{2\pi} \int_0^{2\pi} f_D(L, G, \ell, g) d\ell.$$

These have been computed in [3], and are given by

$$\begin{aligned}\bar{f}_L &= -\frac{1}{G^7} \left(8 + \frac{73}{3} e^2 + \frac{37}{12} e^4 \right), \\ \bar{f}_G &= -\frac{1}{L^3 G^4} (8 + 7e^2), \\ \bar{f}_\ell &= 0, \quad \bar{f}_g = 0.\end{aligned}\tag{10}$$

In order to study the dynamics of the system (7) at resonance, we will apply the method of averaging. We note here that averaging over the fast angle ℓ and the time t gives the correct approximate dynamics for most initial conditions via Neishtadt's theorem as explained in our previous paper [3]. Here we are interested in the orbits that are captured into resonance. To study them, we consider partial averaging at each resonance.

Let us fix the value of L at the $(m : n)$ resonance, say $L = L_*$ with $m/L_*^3 = n\Omega$, and consider the deviation of L from the resonance manifold. To measure this deviation, we introduce a new variable \mathcal{D} given by

$$L = L_* + \epsilon^{1/2} \mathcal{D} \tag{11}$$

and a new angular variable φ by

$$\ell = \frac{1}{L_*^3} t + \varphi = \frac{n\Omega}{m} t + \varphi.$$

The scale factor $\epsilon^{1/2}$ ensures that, after changing to the new variables in (7), the resulting equations for $\dot{\mathcal{D}}$ and $\dot{\varphi}$ have the same order in the new small parameter $\epsilon^{1/2}$ and therefore the system is in the correct form for averaging. These new coordinates are standard choices in the mathematical literature (for more details see, for example, [16, 18]). It is important to emphasize here that the small parameter in the actual dynamics is ϵ ; however, the small parameter turns out to be $\epsilon^{1/2}$ in this case for the averaged dynamics.

To effect the coordinate transformation, we use the expansion

$$\frac{1}{L^3} = \frac{1}{L_*^3} \left[1 - \epsilon^{1/2} \frac{3\mathcal{D}}{L_*} + \epsilon \frac{6\mathcal{D}^2}{L_*^2} + O(\epsilon^{3/2}) \right] \tag{12}$$

and find

$$\begin{aligned}\dot{\mathcal{D}} &= -\epsilon^{1/2} F_{11} - \epsilon \mathcal{D} F_{12} + O(\epsilon^{3/2}), \\ \dot{G} &= -\epsilon F_{22} + O(\epsilon^{3/2}), \\ \dot{\varphi} &= -\epsilon^{1/2} \frac{3}{L_*^4} \mathcal{D} + \epsilon \left(\frac{6}{L_*^5} \mathcal{D}^2 + F_{32} \right) + O(\epsilon^{3/2}), \\ \dot{g} &= \epsilon F_{42} + O(\epsilon^{3/2}),\end{aligned}\tag{13}$$

where the $F_{ij}(G, n\Omega t/m + \varphi, g, t)$ are defined such that the first index refers to the equation in which it appears and the second index refers to the perturbation order in powers of $\epsilon^{1/2}$ that is employed. These quantities are given by

$$\begin{aligned}F_{11} &:= \frac{\partial \mathcal{H}_{\text{ext}}}{\partial \ell} \left(L_*, G, \frac{n\Omega}{m} t + \varphi, g, t \right) - \Delta f_L \left(L_*, G, \frac{n\Omega}{m} t + \varphi, g \right), \\ F_{12} &:= \frac{\partial^2 \mathcal{H}_{\text{ext}}}{\partial L \partial \ell} \left(L_*, G, \frac{n\Omega}{m} t + \varphi, g, t \right) - \Delta \frac{\partial f_L}{\partial L} \left(L_*, G, \frac{n\Omega}{m} t + \varphi, g \right), \\ F_{22} &:= \frac{\partial \mathcal{H}_{\text{ext}}}{\partial g} \left(L_*, G, \frac{n\Omega}{m} t + \varphi, g, t \right) - \Delta f_G \left(L_*, G, \frac{n\Omega}{m} t + \varphi, g \right),\end{aligned}\tag{14}$$

$$F_{32} := \frac{\partial \mathcal{H}_{\text{ext}}}{\partial L} \left(L_*, G, \frac{n\Omega}{m}t + \varphi, g, t \right) + \Delta f_\ell \left(L_*, G, \frac{n\Omega}{m}t + \varphi, g \right),$$

$$F_{42} := \frac{\partial \mathcal{H}_{\text{ext}}}{\partial G} \left(L_*, G, \frac{n\Omega}{m}t + \varphi, g, t \right) + \Delta f_g \left(L_*, G, \frac{n\Omega}{m}t + \varphi, g \right).$$

The system (13) is $2\pi m/\Omega$ periodic in the temporal variable—since \mathcal{H}_{ext} is $2\pi/\Omega$ periodic in time—and is in time-periodic standard form. Anticipating our intention to average to second order, we will apply an averaging transformation (for a detailed exposition see [18]). It is the characteristic property of this transformation that it automatically renders system (13) in a form such that to lowest order the new system is exactly the first-order averaged system and the second-order averaged system can be simply obtained by averaging the new system (cf appendix B). To obtain the desired transformation, we define

$$\bar{F}_{ij} := \frac{\Omega}{2\pi m} \int_0^{2\pi m/\Omega} F_{ij} \left(G, \frac{n\Omega}{m}s + \varphi, g, s \right) ds,$$

and the deviation from the mean for F_{11}

$$\lambda(G, \varphi, g, t) := F_{11} \left(G, \frac{n\Omega}{m}t + \varphi, g, t \right) - \bar{F}_{11}. \quad (15)$$

Furthermore, we define $\Lambda(G, \varphi, g, t)$ to be the antiderivative of $\lambda(G, \varphi, g, t)$ with respect to t with the additional property that the average of Λ should vanish, i.e.

$$\int_0^{2\pi m/\Omega} \Lambda(G, \varphi, g, s) ds = 0.$$

Moreover, we note that both λ and $\partial\Lambda/\partial\varphi$ have zero averages. Our averaging transformation is given by

$$\mathcal{D} = \widehat{\mathcal{D}} - \epsilon^{1/2} \Lambda(\widehat{G}, \widehat{\varphi}, \widehat{g}, t), \quad G = \widehat{G}, \quad \varphi = \widehat{\varphi}, \quad g = \widehat{g}.$$

The averaging transformation is constructed so that its average becomes the identity transformation.

Let us observe that if G, φ and g depend on t as solutions of the system (13), then

$$\dot{\Lambda} = \lambda - \epsilon^{1/2} \left(\frac{3\mathcal{D}}{L_*^4} \right) \frac{\partial \Lambda}{\partial \varphi} + O(\epsilon).$$

After applying the averaging transformation, we find that the system (13) takes the form

$$\begin{aligned} \dot{\widehat{\mathcal{D}}} &= -\epsilon^{1/2} \bar{F}_{11} - \epsilon \widehat{\mathcal{D}} \left(F_{12} + \frac{3}{L_*^4} \frac{\partial \Lambda}{\partial \varphi} \right) + O(\epsilon^{3/2}), \\ \dot{\widehat{G}} &= -\epsilon F_{22} + O(\epsilon^{3/2}), \\ \dot{\widehat{\varphi}} &= -\epsilon^{1/2} \frac{3}{L_*^4} \widehat{\mathcal{D}} + \epsilon \left(\frac{6}{L_*^5} \widehat{\mathcal{D}}^2 + F_{32} + \frac{3}{L_*^4} \Lambda \right) + O(\epsilon^{3/2}), \\ \dot{\widehat{g}} &= \epsilon F_{42} + O(\epsilon^{3/2}). \end{aligned} \quad (16)$$

Finally, we drop the $O(\epsilon^{3/2})$ terms in (16) and average the remaining truncated system to obtain the *second-order partially averaged system*

$$\begin{aligned} \dot{\widetilde{\mathcal{D}}} &= -\epsilon^{1/2} \bar{F}_{11} - \epsilon \widetilde{\mathcal{D}} \bar{F}_{12}, \\ \dot{\widetilde{G}} &= -\epsilon \bar{F}_{22}, \\ \dot{\widetilde{\varphi}} &= -\epsilon^{1/2} \frac{3}{L_*^4} \widetilde{\mathcal{D}} + \epsilon \left(\frac{6}{L_*^5} \widetilde{\mathcal{D}}^2 + \bar{F}_{32} \right), \\ \dot{\widetilde{g}} &= \epsilon \bar{F}_{42}. \end{aligned} \quad (17)$$

This system is the averaged form of system (13) after dropping its $O(\epsilon^{3/2})$ terms; however, this coincidence is fortuitous in this case. In general, one has to employ an averaging transformation in order to obtain the second-order averaged system.

To explain the evolutionary dynamics at resonance, we will replace the actual dynamical equations by the second-order partially averaged system. As explained in appendix B, this is a reasonable approximation over a limited time-scale. We remark that although the second-order partially averaged system will be used to explain some of the features of our model system near its resonances, the actual dynamics predicted by our model is certainly much more complex than the averaged equations reveal. In particular, we expect that near the resonances—perhaps in other regions of the phase space as well—there are chaotic invariant sets and, therefore, transient chaotic motions [3]. The averaged system is nonlinear and could, in general, exhibit chaos; however, we have not encountered chaos in the second-order averaged equations obtained from the model under consideration here.

It remains to compute \bar{F}_{ij} , where F_{ij} are defined in (14). For this, we recall equation (8) and set $\ell = n\Omega t/m + \tilde{\varphi}$, expand the trigonometric terms in the Fourier series using trigonometric identities and then average over the variable t . The required averages involving the external perturbation can be computed from the average of \mathcal{H}_{ext} . In fact, after some computation, we find that

$$\begin{aligned}\bar{\mathcal{H}}_{\text{ext}} &:= \frac{\Omega}{2\pi m} \int_0^{2\pi m/\Omega} \mathcal{H}_{\text{ext}}\left(L_*, \tilde{G}, \frac{n\Omega}{m}t + \tilde{\varphi}, \tilde{g}, t\right) dt \\ &= T_c(L_*, \tilde{G}, \tilde{g}) \cos m\tilde{\varphi} + T_s(L_*, \tilde{G}, \tilde{g}) \sin m\tilde{\varphi},\end{aligned}$$

where, for $n = 1$,

$$\begin{aligned}T_c &:= \frac{1}{4}L^4\Omega^2[\alpha A_m(e) \cos 2g + \beta A_m(e) \sin 2g \cos \rho - \beta B_m(e) \cos 2g \sin \rho], \\ T_s &:= \frac{1}{4}L^4\Omega^2[-\alpha B_m(e) \sin 2g + \beta A_m(e) \sin 2g \sin \rho + \beta B_m(e) \cos 2g \cos \rho],\end{aligned}\tag{18}$$

and for $n \neq 1$, $\bar{\mathcal{H}}_{\text{ext}} = 0$ so that in this case we can define $T_c = T_s = 0$.

The averages of f_D , $D \in \{L, G, \ell, g\}$, are given in (10). The terms involving radiation damping that appear in the partially averaged system are obtained from these expressions by Taylor expansion about the resonant orbit using equation (11). For example, we will use

$$\Gamma(G) := \bar{f}_L|_{L=L_*} = -\frac{1}{G^7} \left(8 + \frac{73}{3}e^2 + \frac{37}{12}e^4\right)|_{e^2=1-G^2/L_*^2}$$

and the average of $\partial f_L / \partial L$ at resonance given by

$$\left. \frac{\partial}{\partial L} \bar{f}_L \right|_{L=L_*} = -\frac{1}{3L_*^3 G^5} (146 + 37e^2)|_{e^2=1-G^2/L_*^2}.$$

The second-order partially averaged system (17) is thus given explicitly by

$$\begin{aligned}\dot{\mathcal{D}} &= -\epsilon^{1/2} \left[-mT_c \sin m\varphi + mT_s \cos m\varphi + \frac{\Delta}{G^7} \left(8 + \frac{73}{3}e^2 + \frac{37}{12}e^4\right) \right] \\ &\quad -\epsilon \mathcal{D} \left[-m \frac{\partial T_c}{\partial L} \sin m\varphi + m \frac{\partial T_s}{\partial L} \cos m\varphi + \frac{\Delta}{3L_*^3 G^5} (146 + 37e^2) \right], \\ \dot{G} &= -\epsilon \left[\frac{\partial T_c}{\partial g} \cos m\varphi + \frac{\partial T_s}{\partial g} \sin m\varphi + \frac{\Delta}{L_*^3 G^4} (8 + 7e^2) \right], \\ \dot{\varphi} &= -\epsilon^{1/2} \frac{3}{L_*^4} \mathcal{D} + \epsilon \left(\frac{6}{L_*^5} \mathcal{D}^2 + \frac{\partial T_c}{\partial L} \cos m\varphi + \frac{\partial T_s}{\partial L} \sin m\varphi \right), \\ \dot{g} &= \epsilon \left(\frac{\partial T_c}{\partial G} \cos m\varphi + \frac{\partial T_s}{\partial G} \sin m\varphi \right),\end{aligned}\tag{19}$$

where we have dropped the tildes. It is clear that L in the expressions involving T_c , T_s and e must be replaced by L_* , the value of L at resonance.

Having derived the equations for the averaged dynamics (19), we now turn our attention to the consequences of these equations and the comparison of predictions based on them with the actual dynamics given by (4).

3. First-order averaged dynamics

The first-order partially averaged system, obtained from (19) by dropping the $O(\epsilon)$ terms, is given by

$$\begin{aligned}\dot{D} &= -\epsilon^{1/2}[-mT_c \sin m\varphi + mT_s \cos m\varphi - \Delta\Gamma(G)], \\ \dot{G} &= 0, \\ \dot{\varphi} &= -\epsilon^{1/2}\left(\frac{3}{L_*^4}\right)\mathcal{D}, \\ \dot{g} &= 0.\end{aligned}\tag{20}$$

In this approximation, the variables G and g are constants fixed by the initial conditions while the remaining system in \mathcal{D} and φ is equivalent to a pendulum-type equation with torque, namely,

$$\ddot{\varphi} + \frac{3\epsilon}{L_*^4}(mT_c \sin m\varphi - mT_s \cos m\varphi) = -\frac{3\epsilon}{L_*^4} \Delta\Gamma(G).\tag{21}$$

We also have a second-order differential equation—a harmonic oscillator with slowly varying frequency—for the deviation \mathcal{D} given by

$$\ddot{\mathcal{D}} + \epsilon w^2 \mathcal{D} = 0,\tag{22}$$

where

$$w := \left[\frac{3m^2}{L_*^4} (T_c \cos m\varphi + T_s \sin m\varphi) \right]^{1/2}.\tag{23}$$

These results can be justified formally if they are recast in terms of a new temporal variable given by $\epsilon^{1/2}t$; however, we use t in order to facilitate comparison with the actual dynamics.

To show that (22) is an oscillator, we must show that w is a real number. To this end, we suppose that during capture into the resonance the orbit is near an elliptic region of the first-order partially averaged system (20). This system is Hamiltonian with an effective energy of the form

$$-\epsilon^{1/2}\left[\frac{1}{2}\left(\frac{3}{L_*^4}\right)\mathcal{D}^2 + U(\varphi)\right],$$

where U represents the effective potential energy given by

$$U := -(T_c \cos m\varphi + T_s \sin m\varphi) + (\Delta\Gamma)\varphi.$$

If $(\mathcal{D}, \varphi) = (0, \varphi_0)$ is an elliptic rest point of the first-order partially averaged system; then, $U'(\varphi_0) = 0$ and $U''(\varphi_0) > 0$, where a prime denotes differentiation with respect to φ . It follows that

$$U''(\varphi_0) = m^2(T_c \cos m\varphi_0 + T_s \sin m\varphi_0),$$

so that $w_0, w_0 := [3U''(\varphi_0)]^{1/2}/L_*^2$, must be real.

To show that the frequency $\xi := \epsilon^{1/2}w$ is slowly varying, we differentiate this frequency with respect to time to obtain

$$\dot{\xi} = -\epsilon \frac{9m^3}{2L_*^8 w} (T_s \cos m\varphi - T_c \sin m\varphi) \mathcal{D} + O(\epsilon^{3/2}).$$

It follows from the first-order averaged equations that $\varphi - \varphi_0$ is expected to be of the order of unity; thus, ξ is nearly constant over a time-scale of order $\epsilon^{-1/2}$ since $\dot{\xi}$ is proportional to ϵ . In particular, \mathcal{D} varies on the time-scale $\epsilon^{1/2}t$. Inspection of equations (21) and (22) reveals that while \mathcal{D} is predominantly a simple harmonic oscillator with frequency $\xi_0 = \epsilon^{1/2}w_0$, the motion of φ in time could be rather complicated involving essentially all harmonics of ξ_0 . Therefore, φ cannot in general be considered a slow variable in time.

Librational motions (periodic motions in the phase plane) of the pendulum-type averaged equation (21) correspond to orbits of the original system that are captured into the resonance. On the other hand, if there are no librational motions, then all orbits pass through the resonance. Thus, we observe a necessary condition for capture: the pendulum system must have rest points in its phase plane. The rest points of the first-order averaged system are given by $\mathcal{D} = 0$ and $\varphi = \varphi_0$, with

$$R \sin(m\varphi_0 + \eta) = -\Delta\Gamma, \quad (24)$$

where $mT_c = R \cos \eta$ and $mT_s = -R \sin \eta$. As an immediate consequence, we have the following proposition: *for the $(m : n)$ resonance, if $n \neq 1$, there is no capture into resonance.* On the other hand, for $n = 1$, if there are librational motions, then we must have $\Delta|\Gamma/R| \leq 1$. These observations suggest that in the presence of sufficiently strong radiation damping, i.e. for Δ sufficiently large, there are no librational motions and, as a result, each orbit will pass through all the resonant manifolds that it encounters. In particular, since $L = a^{1/2}$, the semimajor axis of the corresponding osculating ellipse will collapse to zero. Moreover, capture is only possible for $(m : n)$ resonances with $n = 1$ when $\Delta|\Gamma/R| \leq 1$. In this case, if $\Delta|\Gamma/R| < 1$, then the rest points in the phase plane of the pendulum-type equation (21) at the resonance are all nondegenerate. This is precisely Neishtadt's condition *B*.

The quantities Γ and R depend (nonlinearly) on the variables (L, G, g) as well as the parameters of the system; therefore, the precise range of their ratio Γ/R is difficult to specify, in general. However, the value of this ratio can be determined numerically. In fact, to find orbits that are captured into resonance as displayed in figures 1–3, we use the first-order averaged system. A rest point of the first-order system corresponds to a ‘fixed’ resonant orbit with $\mathcal{D} = 0$ and constant G, g , and $\varphi = \varphi_0$. The main characteristics of these orbits do not change with respect to the slow variable $\epsilon^{1/2}t$; that is, the resonant orbits are essentially fixed only over a time-scale of order $\epsilon^{-1/2}$. After choosing G and g , we solve for φ_0 at a rest point and then test to see if the resulting resonant orbit corresponds to a libration point of the first-order averaged system (e.g. w_0^2 must be positive). If it does, we convert the point with coordinates (L_*, G, φ_0, g) to polar coordinates and then numerically integrate our model (4) backward in time from this starting value. When the backward integration in time is carried out over a sufficiently long time interval, the orbit is expected to leave the vicinity of the resonance. After this occurs, we integrate forward in time to obtain an orbit of (4) that is captured into the resonance.

The first-order partially averaged system (20) is Hamiltonian; therefore, we do not expect that its dynamics would give a complete picture of the average dynamics near a resonance for our *dissipative* system. In particular, the librational motions of the pendulum-like system are not structurally stable. Indeed, the phase space for the full four-dimensional

Figure 2. The plots are for system (4) with parameter values $\epsilon = 10^{-4}$, $\delta/\epsilon = 10^{-3}$, $\alpha = 1$, $\beta = 0$, $\rho = 0$, and $\Omega = 1$. (a) $L = a^{1/2}$ versus time for the initial conditions $(p_r, p_\theta, r, \theta)$ equal to $(-0.007485536, 0.850305, 2.758946, 0.97661369282041)$. (b) Eccentricity versus time and (c) G versus L . Here, $L_* \approx 1.2599$ corresponds to a $(2 : 1)$ resonance, $2/L_*^3 = \Omega$.

system (20) is foliated by invariant two-dimensional subspaces parametrized by the variables G and g . If a librational motion exists in a leaf of the foliation, then the corresponding rest points, the elliptic rest point and the hyperbolic rest point (or points) at the boundary of the librational region for the associated pendulum-like system, are degenerate in the four-dimensional phase space of the first-order averaged system; their linearizations have two zero eigenvalues corresponding to the directions normal to the leaf. In the second-order partially averaged system, viewed as a small perturbation of (20), we expect that only a finite number of the degenerate rest points survive. These correspond to the continuable periodic solutions described in [3]. We expect the corresponding perturbed rest points to be hyperbolic. As a result, they persist even when higher-order effects are added. The dimensions and positions of the stable and unstable manifolds of these rest points determine the average motion near the resonance. In particular, if one of these rest points is a hyperbolic sink, then there is an open set of initial conditions that correspond to orbits *permanently* captured into resonance. Our numerical experiments have provided no evidence for this behaviour. However, another possibility—that is consistent with our numerical experiments—is that a rest point of the perturbed system in phase space is stable along two directions but unstable in the remaining two directions. Thus a trajectory with its initial point near the corresponding stable manifold will be captured into resonance and undergo librational motions near the resonant manifold until it spirals outward along the unstable manifold.

Figure 3. The plots are for system (4) with parameter values $\epsilon = 10^{-4}$, $\delta/\epsilon = 10^{-3}$, $\alpha = 1$, $\beta = 0$, $\rho = 0$, and $\Omega = 1$. (a) $L = a^{1/2}$ versus time for the initial conditions $(p_r, p_\theta, r, \theta)$ equal to $(-0.09951, 1.56904, 2.33813, 2.32909)$. (b) Eccentricity versus time and (c) G versus L . Here, $L_* \approx 1.5874$ corresponds to a $(4 : 1)$ resonance, $4/L_*^3 = \Omega$.

4. Dynamical evolution during resonance

The dynamics of system (19) is expected to give a close approximation of the near resonance behaviour of our original model (4) over a time-scale of order $\epsilon^{-1/2}$. In particular, a basic open problem is the following: determine the positions of the rest points and the corresponding stable and unstable manifolds of (19). A solution of this problem would provide the information needed to analyse the most important features of the behaviour of the orbits that pass through the resonance as well as those that are captured by the resonance. Unfortunately, rigorous analysis of the dynamics in the four-dimensional phase space of system (19) seems to be very difficult at present. Thus, in lieu of a complete and rigorous analysis of the dynamics, we will show how to obtain useful information from approximations of the second-order partially averaged system.

A typical example of the behaviour of the orbit as it passes through a $(1 : 1)$ resonance is depicted in figure 1. The semimajor axis undergoes librations of increasing amplitude around the resonant value. Furthermore, the eccentricity of the orbit generally decreases while the orbit is trapped.

We propose to analyse the oscillations of \mathcal{D} by using the $O(\epsilon)$ approximation of the second-order differential equation for \mathcal{D} derived from the second-order partially averaged

equations (19). In fact, a simple computation yields the following differential equation:

$$\ddot{\mathcal{D}} + \epsilon\gamma\dot{\mathcal{D}} + \epsilon w^2\mathcal{D} = 0, \quad (25)$$

where

$$\gamma := m \left(\frac{\partial T_s}{\partial L} \cos m\varphi - \frac{\partial T_c}{\partial L} \sin m\varphi \right) + \frac{\Delta}{3L^3 G^5} (146 + 37e^2) \quad (26)$$

is evaluated at $L = L_*$ in equation (25) and w is given by equation (23). Similarly, the second-order partially averaged system (19) can be used to derive an equation for the temporal evolution of φ to order ϵ ; in fact, the resulting equation turns out to be equation (21) with an additional damping (or anti-damping) term.

It is clear from inspection of the differential equation (25) that $L = L_* + \epsilon^{1/2}\mathcal{D}$ oscillates about its resonant value L_* with a libration frequency given approximately by $\xi_0 = \epsilon^{1/2}w_0$. The magnitude of this frequency is in agreement with our numerical results to within a few per cent for the case of resonance trapping depicted in figure 1. Moreover, the amplitude of the oscillations will increase (decrease) if $\gamma < 0$ ($\gamma > 0$).

The sign of γ varies with the choice of parameters, variables and the order of the resonance. Our numerical experiments—which have been by no means exhaustive—indicate that the (1 : 1) resonance for the linearly polarized incident wave with $\alpha = 1$ and $\beta = 0$ is special in that γ is negative at the elliptic rest points of the first-order averaged system. However, for a resonance with order $m > 1$, γ is not of fixed sign. Nevertheless, our numerical experiments indicate that the amplitude of librations generally increases over a long time-scale (cf figure 2). Figures 2 and 3 illustrate the apparent richness of the evolutionary dynamics near resonances with $m > 1$. It should be emphasized that the damped (or anti-damped) oscillator (25) approximates the actual dynamics only over a time-scale of order $\epsilon^{-1/2}$ (cf appendix B).

To obtain an approximate equation for the envelope of the oscillations, we consider a time-dependent change of variables for the oscillator (25) defined by the relation

$$\mathcal{D} = V e^{-(\epsilon/2) \int_0^t \gamma(s) ds}. \quad (27)$$

After a routine calculation, we obtain the differential equation

$$\ddot{V} + \epsilon w^2 V = O(\epsilon^{3/2}). \quad (28)$$

Thus, to order ϵ , $V(t)$ in equation (27) is the solution of a harmonic oscillator equation with a slowly varying frequency $\xi = \epsilon^{1/2}w$. In fact, equation (28) is identical to the oscillator (22) with frequency ξ obtained from the first-order averaged system. The solution $\mathcal{D}(t)$ of the second-order equation (25) in this approximation is obtained by modulating the amplitude of V .

We note that if γ and w are constants, then equation (27) reduces to

$$\mathcal{D}(t) = \mathcal{A} e^{-\epsilon\gamma t/2} \cos(\epsilon^{1/2}wt + \tau),$$

where \mathcal{A} and τ are constants depending on the initial conditions; this is the standard result for the damped (or anti-damped) harmonic oscillator with constant coefficients.

Equation (27) certainly agrees qualitatively with the numerical experiments reported in figures 1–3. To check the accuracy quantitatively, we integrated system (4) numerically and simultaneously evaluated the integral of γ in order to obtain an approximation for the envelope of $\mathcal{D}(t)$. Over an interval of time of length 691, which is of order $\epsilon^{-1/2}$, the value of \mathcal{D} at its maximum predicted from equation (27) differs from the value obtained by numerical integration of the differential equations by only a few per cent (actually 2.5%).

The error in the comparison of the two values for the envelope of \mathcal{D} grows slowly over time; in fact, it remains less than 20% over a time interval of length 9000.

The evolutionary dynamics near resonance is characterized by librational motions described above as well as variations in angular momentum. Our numerical experiments suggest considerable variation in the angular momentum while the orbit is trapped in resonance. The remainder of this section is devoted to a theoretical explanation of this phenomenon.

During the time that an orbit is captured into resonance, we expect that on average it will reside near an elliptic rest point of the first-order partially averaged system. Thus, we expect the dynamical variables to satisfy equation (24) approximately while the orbit is trapped. We will show how to determine the dynamical behaviour of the angular momentum G under this assumption. In particular, for the (1 : 1) resonance, we claim that $\dot{G} > 0$, that is, the orbital angular momentum increases.

It is easy to show that

$$\begin{aligned}\frac{\partial T_c}{\partial g} - 2T_s &= -\frac{1}{2L_*^2}[\alpha \sin 2g - \beta \cos(2g + \rho)]S_m(e), \\ \frac{\partial T_s}{\partial g} + 2T_c &= \frac{1}{2L_*^2}[\alpha \cos 2g + \beta \sin(2g + \rho)]S_m(e),\end{aligned}$$

where

$$S_m(e) := m^2[A_m(e) - B_m(e)].$$

After substituting these identities as well as condition (24) into the expression for \dot{G} in (19), we find that

$$\dot{G} = -\epsilon[P_m(e) + L_*^{-2}S_m(e)Q_m], \quad (29)$$

where, after some manipulation using the relation $e = (1 - G^2/L_*^2)^{1/2}$,

$$\begin{aligned}P_m(e) &:= \frac{\Delta}{G^7} \left[(1 - e^2)^{3/2}(8 + 7e^2) - \frac{2}{m} \left(8 + \frac{73}{3}e^2 + \frac{37}{12}e^4 \right) \right], \\ Q_m &:= \frac{1}{2}[\alpha \sin(m\varphi - 2g) + \beta \cos(m\varphi - 2g - \rho)].\end{aligned}$$

The function $S_m(e) \rightarrow 0$ as $e \rightarrow 0$; therefore, it is clear that $\dot{G} > 0$ near $e = 0$ as long as $P_m(e) < 0$. We have $P_1(e) < -8\Delta/G^7$ for $0 < e < 1$. For $m = 2$, we have $P_2(e) < 0$, but $P_2(0) = 0$, while for $m > 2$, we have $P_m(e) > 0$ near $e = 0$. Our conclusion is that near the (1 : 1) resonance, we can expect $\dot{G} > 0$ during capture provided the osculating ellipse is not too eccentric. The other cases are more delicately balanced. However, for a specific choice of parameters and for a specific resonance, one can use equation (29) to predict the behaviour of G near the resonance.

Consider, for instance, the system (4) with the following parameter values: $\epsilon = 10^{-4}$, $\Delta = \delta/\epsilon = 10^{-3}$, $\alpha = 1$, $\beta = 0$, $\rho = 0$ and $\Omega = 1$. The orbit, as depicted in figure 1, with initial conditions given by

$$(p_r, p_\theta, r, \theta) = (0.2817, 0.6389, 1.6628, 2.9272)$$

appears to be trapped in a (1 : 1) resonance with a sojourn time of approximately 40 000. Moreover, during this period of time the angular momentum appears to increase from approximately 0.66 to 0.95. To demonstrate that our theoretical scheme using the second-order partially averaged system agrees with our numerical results, let us determine the time-scale over which the angular momentum changes from 0.78 to 0.95. According to the

numerical integration of system (4) this occurs over about 32 700 time units, whereas our approximate analysis of the second-order partially averaged system predicts a time-scale of

$$-\frac{1}{\epsilon} \int_{0.78}^{0.95} [P_1((1 - G^2/L_*^2)^{1/2})]^{-1} dG \approx 34\,200,$$

a time that is within 5% of the value given by our numerical experiment. In this integral, we have used the fact that in equation (29), the term $L_*^{-2} S_1(e) Q_1$ is small compared with $P_1(e)$.

It should be clear from the results of this section that—by employing the second-order partially averaged system—we have been able to provide theoretical explanations for the behaviours of semimajor axis a and eccentricity e of the orbit that is trapped in resonance. The basic dynamical equations for our model are only valid to order ϵ , since physical effects of higher order have been neglected in equation (4); therefore, it would be inappropriate to go beyond the second-order averaged system in this case. The averaging method is general, however, and can be carried through to any order.

5. Conclusion

In our previous investigation of the dynamics of a Keplerian binary system that is perturbed by the emission and absorption of gravitational radiation [3], we found in our numerical work interesting instances of dynamical behaviour associated with resonance trapping that could not be deduced in a simple way from the basic equations of our model. We have shown in the present work that removing the ‘fast’ orbital motion at resonance via the procedure of partial averaging of the basic equations results in a new set of equations that can provide an effective theoretical explanation for the dynamical behaviour of the binary system while trapped in resonance.

When the binary system in our model is trapped in a resonance, the semimajor axis of the osculating ellipse oscillates about a fixed value determined by the resonance condition while the external perturbation, in general, exchanges a net amount of angular momentum with the system thus changing the shape of the binary orbit during resonance. We have explicitly demonstrated in this paper that the main characteristics of our model system while it is locked in resonance can be understood on the basis of the second-order partially averaged dynamics.

The averaging procedure developed here could be applied to any dynamical system that is trapped in resonance. Of particular interest would be a generalization of our model that would take the tidal influence of external masses into account as well. Moreover, some of the observed structure in the solar system could be the direct result of evolutionary dynamics while trapped in resonance (see [6, 13, 14]). These issues warrant further investigation.

Appendix A. Delaunay equations of motion

The Delaunay equations of motion for our system are given in [3] as

$$\begin{aligned} \frac{dL}{dt} &= -\epsilon \left(\frac{\partial \mathcal{C}}{\partial \ell} \phi(t) + \frac{\partial \mathcal{S}}{\partial \ell} \psi(t) \right) + \delta f_L, \\ \frac{dG}{dt} &= -\epsilon \left(\frac{\partial \mathcal{C}}{\partial g} \phi(t) + \frac{\partial \mathcal{S}}{\partial g} \psi(t) \right) + \delta f_G, \\ \frac{d\ell}{dt} &= \omega + \epsilon \left(\frac{\partial \mathcal{C}}{\partial L} \phi(t) + \frac{\partial \mathcal{S}}{\partial L} \psi(t) \right) + \delta f_\ell, \end{aligned} \tag{A1}$$

$$\frac{dg}{dt} = \epsilon \left(\frac{\partial \mathcal{C}}{\partial G} \phi(t) + \frac{\partial \mathcal{S}}{\partial G} \psi(t) \right) + \delta f_g,$$

where

$$\phi(t) := \frac{1}{2} \alpha \Omega^2 \cos \Omega t, \quad \psi(t) := \frac{1}{2} \beta \Omega^2 \cos(\Omega t + \rho),$$

and \mathcal{C} and \mathcal{S} are given by equation (9) and

$$\begin{aligned} f_L &= \frac{4}{Lr^3} \left[1 - \frac{16}{3} \frac{L^2}{r} + \left(\frac{20}{3} L^2 - \frac{17}{2} G^2 \right) \frac{L^2}{r^2} + \frac{50}{3} \frac{L^4 G^2}{r^3} - \frac{25}{2} \frac{L^4 G^4}{r^4} \right], \\ f_G &= -\frac{18G}{L^2 r^3} \left(1 - \frac{20}{9} \frac{L^2}{r} + \frac{5}{3} \frac{L^2 G^2}{r^2} \right), \\ f_\ell &= \frac{2 \sin \hat{v}}{e L^3 G r^2} \left[4e^2 + \frac{1}{3} (73G^2 - 40L^2) \frac{1}{r} - 2 \left(1 + \frac{70}{3} L^2 - \frac{29}{2} G^2 \right) \frac{G^2}{r^2} \right. \\ &\quad \left. - \frac{25}{3} \frac{L^2 G^4}{r^3} + 25 \frac{L^2 G^6}{r^4} \right], \\ f_g &= -\frac{2 \sin \hat{v}}{e L^2 r^3} \left[11 + (7G^2 - \frac{80}{3} L^2) \frac{1}{r} - \frac{25}{3} \frac{L^2 G^2}{r^2} + 25 \frac{L^2 G^4}{r^3} \right]. \end{aligned} \quad (\text{A2})$$

The f_D can be expressed, in principle, in terms of Delaunay elements. In fact, expressions of the form r^{-q} and $r^{-q} \sin \hat{v}$ can be expanded as Fourier series in terms of the mean anomaly ℓ (see [7], p 54). For example, the following results are known [7, 20]

$$\frac{L^2}{r} = 1 + 2 \sum_{n=1}^{\infty} J_n(ne) \cos n\ell, \quad (\text{A3})$$

$$\frac{L^4}{r^2} \sin \hat{v} = \frac{(1 - e^2)^{1/2}}{e} \sum_{n=1}^{\infty} 2n J_n(ne) \sin n\ell. \quad (\text{A4})$$

For the calculation of the other similar expressions—and eventually the f_D —see the methods of classical celestial mechanics involving the Bessel functions described in [7, 20]. Only the *averages* of the f_D —calculated in [3] and given in equation (10)—are needed for the purposes of this paper.

Appendix B. The method of averaging

In this section, we give a brief introduction to the method of averaging as it is used in this paper. More detailed accounts can be found in many excellent sources. We suggest [16, 21, 22, 18, 19], as they offer a range of mathematical sophistication as well as diverse points of view.

The method of averaging is usually applied to differential equations in one of several standard forms. In celestial mechanics, perhaps the most common standard form is the ‘angular standard form’

$$\dot{I} = \epsilon f(I, \theta), \quad \dot{\theta} = \omega(I) + \epsilon g(I, \theta),$$

where I is an m -dimensional variable, θ is an n -dimensional angular variable, both f and g are 2π periodic in θ and ϵ is a small parameter. This form is often obtained after a model of disturbed two-body motion is expressed in the action-angle variables appropriate for the unperturbed Kepler problem as in equation (7). The second form is the ‘time-periodic standard form’

$$\dot{x} = \epsilon F(x, t), \quad (\text{B1})$$

where x is an m -dimensional variable and F is T -periodic in time. This form is obtained for many different physical problems. In particular, in our case (i.e. equation (13)) the small parameter is $\epsilon^{1/2}$ and the equation of motion is a Taylor series in $\epsilon^{1/2}$. Of course, the time-periodic standard form can be viewed as a special case of the angular standard form by introducing a new one-dimensional angular variable:

$$\dot{x} = \epsilon F^*(x, \theta), \quad \dot{\theta} = \frac{2\pi}{T}.$$

However, it is useful to separate the two cases. The averaging principle is often applied to differential equations after they are transformed to one of the above standard forms. It consists of approximating a solution of the angular standard form by the corresponding solution (with the same initial conditions) of the averaged system

$$\dot{J} = \epsilon \frac{1}{(2\pi)^n} \int_0^{2\pi} f(J, \theta) d\theta$$

or, for the time-periodic standard form, by the equation

$$\dot{y} = \epsilon \frac{1}{T} \int_0^T F(y, t) dt.$$

The validity of the approximation produced by the averaging principle is often left unverified. However, as many examples show, the averaging principle is not valid in general. Thus, a careful analysis of a physical problem must always deal with this issue. Fortunately, the problem has been treated in great detail in the mathematical literature. Many useful and rigorous results are now available.

The basic result involves only one angular variable; that is, it pertains either to the time-periodic standard form or to the case when θ is one dimensional in the angular standard form. The averaging theorem asserts in this case (with appropriate smoothness of the functions involved) that the averaged solution approximates the original solution with an error of order ϵ on a time-scale of order $1/\epsilon$; for example, if $x(0) = y(0)$, then there are constants C_1 and C_2 that do not depend on ϵ such that

$$|x(t) - y(t)| < C_1 \epsilon, \quad 0 \leq t \leq \frac{C_2}{\epsilon}.$$

Furthermore, there is a change of coordinates (the averaging transformation) of the form $x = z + \epsilon K(z, t)$ such that

$$\dot{z} = \epsilon \frac{1}{T} \int_0^T F(z, t) dt + \epsilon^2 F_2(z, t) + \epsilon^3 \mathcal{F}(z, t, \epsilon). \quad (\text{B2})$$

This is exactly the idea that we use to obtain the averaging transformation (15): the purpose of the averaging transformation is to render the transformed equation in a form that is already averaged to first order. The second-order averaged system is then

$$\dot{u} = \epsilon \frac{1}{T} \int_0^T F(u, t) dt + \epsilon^2 \frac{1}{T} \int_0^T F_2(u, t) dt. \quad (\text{B3})$$

That is, once the differential equation (B1) is transformed into the exact form (B2) using an averaging transformation, the second-order averaged system is simply obtained from (B2) by averaging the second term and dropping terms of higher order. The averaging transformation can be uniquely defined as in section 2; indeed, this leads to a unique second-order averaged system. It turns out that a solution $u(t, u_0, \epsilon)$ of this system with initial condition $u(0, u_0, \epsilon) = u_0$ can be used to approximate the corresponding solution of equation (B1)

with an error of order ϵ^2 on a time-scale of order $1/\epsilon$. More precisely, there are constants $c_1 > 0$ and $c_2 > 0$ such that

$$|x(t, u_0 + \epsilon K(u_0, 0), \epsilon) - [u(t, u_0, \epsilon) + \epsilon K(u(t, u_0, \epsilon), t)]| < c_1 \epsilon^2$$

for $0 \leq t \leq c_2/\epsilon$. Thus, the second-order averaged system gives a second-order approximation to the full dynamics. We expect that the qualitative features of the dynamics of the original system, for example, the stability of its rest points, are reflected in the second-order averaged system. While this is not always the case, it is a reasonable working hypothesis for the analysis of our model. The *partially* averaged system is the result of the application of the method of averaging to the dynamical system at *resonance*. Some of the delicate mathematical issues associated with higher-order averaging, together with an analysis of resonance trapping for a one degree of freedom model, are discussed in [23].

It is important to note that for systems in angular standard form with more than one angle the averaging principle is not valid in general. In fact, it is exactly the orbits for which the averaging principle is invalid that correspond to the orbits that are captured into resonances. In [3], we have discussed the implications of the result of Neishtadt, which asserts that, under additional assumptions that hold for our model, the set of initial conditions corresponding to capture has a measure of order $\epsilon^{1/2}$. Resonance trapping is therefore proved to be rare for the case of two angles unless Neishtadt's hypotheses are violated (see [17] for a discussion). Rigorous results about the validity of the averaging method for the case of more than two angles are much weaker than Neishtadt's result (cf [16]).
